Abstract

This appendix documents the estimation of individual-level bank deposit wealth for the Swedish population over the period 1999–2015. The core measurement challenge arises from changes in the Swedish administrative reporting regime: the deposit balance variable in the interest-income register (KU20) at Statistics Sweden (SCB) is directly observed only through 2007, after which the abolition of the wealth tax ended financial-stock reporting. To train a supervised prediction model, we exploit a temporary expansion of reporting requirements in 2006–2007, when accounts above the balance threshold had to be reported regardless of interest generated. The estimator is a two-stage random forest. The first stage predicts whether an individual holds any bank deposit (the extensive margin); the second predicts the deposit level conditional on participation (the intensive margin). For out-of-sample years, the predicted extensive margin is rank-normalised to the observed 2007 participation share, ensuring that predicted deposit ownership is not distorted by time-varying reporting rules or the declining interest-rate environment. The model is trained on 2007 data and validated against a temporally distinct 2006 holdout. The result is a full-population individual-year panel of imputed deposit balances covering the Swedish tax-filing population, delivered for integration into the household balance sheet.

1 Introduction and Scope

This appendix documents the construction of the bank-deposit component of the MiNA household balance sheet. The object is an individual-year series of predicted end-of-year deposit balances, $W_{i,t}^{\text{Cash}}$, for Swedish residents identified by the intersection of the Total Population Register (RTB) and the Income and Tax Register (IoT), hereafter the resident population, over 1999–2015. The purpose of the appendix is to define the measurement concept, describe the administrative reporting environment that determines when balances are observed, and state the imputation procedure used to construct the series.

Constructing a consistent micro-level deposit series for the Swedish population is complicated by a sharp discontinuity in the administrative reporting environment. The interest-income register, KU20 (Statistics Sweden, 2016b), contains bank-interest records linked to the population and income-tax registers, but the deposit balance variable was reported only through 2007. The abolition of the wealth tax, effective from income year 2008 (Sveriges riksdag, 2007), ended reporting for financial assets and liabilities. After 2007, only flow variables—notably bank-interest income—remain in KU20. Moreover, the set of observed interest reporters contracts mechanically as deposit rates fall: when rates decline, fewer accounts generate sufficient interest to cross the reporting threshold, so that post-2007 KU20 participation is a changing, policy-sensitive sample rather than a stable measure of true deposit ownership.

The estimator is a two-stage random forest trained on 2007 data, the last year with observed balances and part of the temporary broad-reporting regime. Year 2006 is held out as a temporally distinct comparison year under the same broad-reporting regime. The aggregate evidence supports treating the 2006–2007 window as the closest available approximation to full stock coverage in the microdata. Summed observed KU20 deposit balances in 2006 and 2007 are approximately 102.7 and 102.9 percent, respectively, of the household-sector deposit aggregate in the national financial accounts (SCB, 2015b). The 2006–2007 window therefore defines the observed deposit balances concept that anchors the imputation. Applying the 2007-trained estimator to the full individual-year resident population yields the imputed cash-and-deposits component used in the household balance-sheet panel.

The remainder of this appendix is organised as follows. Section 2 describes the data sources and sample construction. Section 3 defines the target variable and formalises the reporting environment that motivates the estimation strategy. Section 4 presents the estimation procedure. Section 5 describes the final output.

2 Data Sources and Sample Construction

2.1 Overview of Data Sources

The primary data source is the KU20 interest-income register (*Kontrolluppgift — Ränteinkomst*), observed in the Kontrolluppgiftsregister (KURU) at (Statistics Sweden, 2016b). KU20 records bank-interest income and, through 2007, end-of-year deposit balances for accounts at Swedish financial institutions. The deposit balance is the main outcome variable for the supervised learning step; bank-interest income is intentionally excluded from the predictor set, for reasons discussed in Section 4.2.

We draw individual-level income and tax variables from the IoT register (*Inkomst- och Taxeringsregistret*; Statistics Sweden (2016b)). The population universe is defined by the year-specific intersection of IoT with the Total Population Register (*Befolkningsregistret (RTB)*; Statistics Sweden (2017)). Municipality of residence is obtained from the Population Register, family structure—spouse cohabitation, number of children, and parental identifiers—is constructed from the Multi-Generation Register (*Flergenerationsregistret*; Statistics Sweden (2015c)) and the household composition register within LISA (Statistics Sweden, 2015d). Educational attainment comes from the Education Register (Statistics Sweden, 2015a), and vehicle ownership from the Vehicle Register (*Fordonsregistret*; Statistics Sweden (2016a)), which serves as a durable-goods proxy.

The predictor set also incorporates debt and housing-market variables constructed in companion balance-sheet appendices. Predicted mortgage debt and mortgage-interest variables come from the companion debt appendix (Sodini and MiDa, 2026b) while total interest expense comes from KU25 records (Statistics Sweden, 2016b). Non-apartment real-estate ownership, transactions, and valuation variables are processed through the companion real-estate valuation appendix (Sodini and MiDa, 2026c). Cooperative apartment ownership and valuations come from the cooperative apartment valuation appendix (Sodini and MiDa, 2026a).

Table 1: Source data used in the construction

Source	Provider	Years	Information contributed
KU20/KURU	Statistics Sweden (2016b)	1999–2015[a]	Bank-interest income; deposit balances (through 2007)
IoT	Statistics Sweden (2016b)	1995–2015	Disposable income, labour income, capital income
RTB	Statistics Sweden (2017)	1999–2015	Population universe
Migration Register (*Flyttflöde*)	Statistics Sweden (2017)	1999–2015	Municipality of residence
Multi-Generation Register	Statistics Sweden (2015c)	Time-stable	Biological and adoptive parental links
LISA / Household Register	Statistics Sweden (2015d)	1999–2015	Household identifiers, family status
Education Register	Statistics Sweden (2015a)	1999–2015	Educational attainment
Vehicle Register	Statistics Sweden (2016a)	1999–2015	Car ownership (durable-goods proxy)
KU25	Statistics Sweden (2016b)	1999–2015	Interest expense on debt
Debt estimation outputs	Sodini and MiDa (2026b)	1999–2015	Predicted mortgage interest, mortgage debt, real-estate features

[a] Effective coverage excludes 2001–2002 (provider identifier unavailable).

2.2 Sample Definition and Construction

The prediction universe for year t is the set of individuals observed in both RTB and IoT, denoted $\mathcal{R}_t$. This intersection excludes non-residents, very young children, and non-tax-filers. Individual-level deposit predictions are constructed for every member of $\mathcal{R}_t$ in each year from 1999 through 2015. Household-level aggregates can be formed downstream by summing over household members, but household aggregation is not part of the primitive target definition.

The supervised learning design exploits the broadening of the reporting window in 2006–2007. Year 2007 serves as the training year: it is the last year in which deposit balances are observed and lies inside the broad-reporting regime, so that low-yield but economically nontrivial balances are more likely to be captured than in the surrounding years. Year 2006 provides a temporally distinct holdout: it shares the same reporting regime as 2007 while remaining out of sample for model fitting, providing a more informative test of temporal transport than random within-year cross-validation.

To construct the observed outcome for 2006–2007, we first de-duplicate and aggregate the cleaned KU20 data to the individual–year–provider level, then sum across providers to obtain each individual's total year-end deposit balance. We exclude records classified as interest on non-bank-account claims, as these fall outside the deposit concept.

For 2006 and 2007, the cleaned and aggregated KU20 balance outcomes are merged onto the full resident population $\mathcal{R}_t$. Individuals with no matching cleaned KU20 balance record are kept in the sample and assigned zero observed deposits and zero bank-interest income. The training and holdout samples therefore represent the full population frame, not only individuals observed in KU20.

3 Key Definitions and Base Variables

The target variable $W_{i,t}^{\text{Cash}}$ is the imputed end-of-year stock of bank deposits held by individual i at the end of year t, measured in SEK.

Let $B_{i,t}^{\text{Cash}}$ denote the true latent stock of bank deposits held by individual i at the end of year t, summed across all deposit accounts and providers. This quantity is not directly observed for the full population in any year. What is observed depends on the administrative reporting regime, which underwent two consequential changes during the sample period.

Under the standard regime (income years through 2005 and from 2008 onward), a KU20 control statement was in principle required when annual bank-interest income at a given provider reached a minimum threshold of only SEK 100. When deposit rates fall, the balance required to trigger a report rises. At an effective deposit rate r_t^{Cash}, the

interest-only frontier is approximately

$$B_t^{\min} \approx \frac{100}{r_t^{\text{Cash}}}. \tag{1}$$

A temporary broadening of the reporting frontier, introduced by legislative amendment (Swedish Parliament, 2005), added a balance-based criterion for income years 2006 and 2007: a control statement was also required when the end-of-year account balance exceeded a separate threshold of SEK 10,000, regardless of interest generated. After 2007, the abolition of the wealth tax removed balance reporting entirely; KU20 continues to record interest flows but no longer provides a stock variable.

A compact representation of the reporting environment is useful for distinguishing the latent deposit stock from its administrative observation rule. Let $B_{i,t,p}^{\text{Cash}}$ denote the latent end-of-year deposit balance of individual i at provider p, and let $I_{i,t,p}^{\text{Cash}}$ denote the associated annual bank-interest income. Let $R_{i,t,p}^{I}$ indicate that a KU20 interest record is filed, and let $R_{i,t,p}^{B}$ indicate that the corresponding balance is observed. Abstracting from timing conventions and small reporting noise, the relevant frontier can be written as

$$R_{i,t,p}^{I} \approx \begin{cases} \mathbf{1}\left\{I_{i,t,p}^{\text{Cash}} \geq 100\right\}, & t \leq 2005, \\ \mathbf{1}\left\{I_{i,t,p}^{\text{Cash}} \geq 100 \text{ or } B_{i,t,p}^{\text{Cash}} \geq 10{,}000\right\}, & t \in \{2006, 2007\}, \\ \mathbf{1}\left\{I_{i,t,p}^{\text{Cash}} \geq 100\right\}, & t \geq 2008, \end{cases} \tag{2}$$

with balance observability given by

$$R_{i,t,p}^{B} \approx R_{i,t,p}^{I} \cdot \mathbf{1}\{t \leq 2007\}. \tag{3}$$

The operator is approximate rather than deterministic: some providers may file records below the statutory frontier, and ordinary reporting and timing noise remains. The formalisation nevertheless captures the key measurement problem, namely that a given latent balance is more likely to be observed when interest rates are high or when the 2006–2007 balance trigger is active. The choice of 2007 as the training year and 2006 as the holdout year is therefore supported both by the reporting rules and by the aggregate coverage checks discussed above.

We denote by $\tilde{B}_{i,t}^{\text{Cash}}$ the deposit stock observable under the broad 2006–2007 reporting regime, aggregated across all providers for individual i. In the training year, this broad-reporting concept can be written as

$$\tilde{B}_{i,2007}^{\text{Cash}} = \sum_p B_{i,2007,p}^{\text{Cash}} \mathbf{1}\left\{I_{i,2007,p}^{\text{Cash}} \geq 100 \text{ or } B_{i,2007,p}^{\text{Cash}} \geq 10{,}000\right\}. \tag{4}$$

This object captures balances reported under either the interest-based or the balance-

based criterion and serves as an economically meaningful approximation of the true latent stock $B_{i,t}^{\text{Cash}}$, though it may undercount very small balances that fall below both reporting thresholds even in the broad regime.

The estimation procedure exploits a hurdle decomposition of $\tilde{B}_{i,t}^{\text{Cash}}$. Define the participation indicator

$$S_{i,t}^{\text{Cash}} = \mathbf{1}\left\{\tilde{B}_{i,t}^{\text{Cash}} > 0\right\}, \tag{5}$$

the conditional participation probability

$$\pi^{\text{Cash}}(\mathbf{x}) = \Pr\left(S_{i,t}^{\text{Cash}} = 1 \;\middle|\; \mathbf{x}_{i,t} = \mathbf{x}\right), \tag{6}$$

and the conditional expected level

$$m^{\text{Cash}}(\mathbf{x}) = \mathbb{E}\left[\tilde{B}_{i,t}^{\text{Cash}} \;\middle|\; S_{i,t}^{\text{Cash}} = 1,\ \mathbf{x}_{i,t} = \mathbf{x}\right], \tag{7}$$

where $\mathbf{x}_{i,t}$ is a vector of observable characteristics described in Section 4.2. The imputed deposit wealth is then

$$W_{i,t}^{\text{Cash}} = \widehat{S}_{i,t}^{\text{Cash}} \cdot \widehat{m}^{\text{Cash}}(\mathbf{x}_{i,t}), \tag{8}$$

where $\widehat{S}_{i,t}^{\text{Cash}}$ is a calibrated extensive-margin indicator and $\widehat{m}^{\text{Cash}}(\cdot)$ is the conditional-balance function estimated from the 2007 training sample. The separation of extensive and intensive margins is economically important: the reporting regime primarily distorts the extensive margin, as low-yield accounts disappear when interest thresholds bind, and a single-stage level regression would conflate participation selection with balance-level prediction.

4 Bank Deposit Estimation Procedure

4.1 Overview of the Procedure

We proceed in four steps to estimate individual-level deposit wealth. Step 1 defines the supervised learning environment by constructing population-level training and holdout samples from the 2006–2007 broad-reporting window. Step 2 assembles a high-dimensional predictor vector from linked administrative registers, designed to proxy for the economic determinants of deposit demand while avoiding information that is mechanically linked to the changing reporting frontier. Step 3 estimates the participation probability $\pi^{\text{Cash}}(\cdot)$ and the conditional level function $m^{\text{Cash}}(\cdot)$ separately using random forests (Breiman, 2001). Step 4 applies the estimated model to the full population in every year 1999–2015, using a rank-normalisation procedure to correct for the mechanically distorted extensive margin.

4.2 Detailed Construction

4.2.1 Step 1: Training Design

As described in Section 2.2, year 2007 serves as the training year and year 2006 as a temporally distinct holdout, both constructed at the population level with non-KU20 reporters assigned $\tilde{B}_{i,t}^{\text{Cash}} = 0$.

4.2.2 Step 2: Predictor Architecture

The predictor vector $\mathbf{x}_{i,t}$ is high-dimensional and designed to proxy for the economic determinants of deposit holding: permanent income, life-cycle position, household structure, leverage, housing-market exposure, and intergenerational resources. The income and life-cycle block draws disposable income, labour income, and capital income from the IoT register, together with one- to four-year lags, three- and five-year moving averages, and first differences to capture income trajectory and income risk. Demographic attributes include age, sex, municipality, educational attainment, and marital status. Household composition is represented by a spouse cohabitation indicator, the number of children, and a young-child flag. Intergenerational and intra-household resources enter through the income, debt, and real-estate variables of spouses, biological parents, and children, capturing family-linked wealth correlations that are informative for individual deposit holdings. The debt and housing block includes total interest expense; predicted mortgage interest and mortgage debt from the companion household-debt appendix (Sodini and MiDa, 2026b); and real-estate ownership characteristics, including property type, holding period, and acquisition or sale events, from the companion real-estate valuation appendix (Sodini and MiDa, 2026c). Finally, vehicle ownership serves as a durable-goods proxy.

A central design restriction is that the baseline estimator excludes contemporaneous bank-interest income from the predictor set. The mapping from observed interest to underlying deposit balances is itself regime-dependent: the economic content of a given interest realisation changes when the reporting frontier shifts or when deposit rates fall. We instead use capital-income constructs that deliberately exclude the deposit-interest component, preserving information about broader financial resources without mechanically reintroducing the reporting distortion.[1]

4.2.3 Step 3: Two-Stage Random Forest Estimation

The implemented estimator is a hurdle-type model estimated in two stages, corresponding to the decomposition in Equation (8).

In the first stage, we estimate the participation function $\pi^{\text{Cash}}(\cdot)$ defined in Equation (6). The binary outcome is whether individual i has a positive deposit balance in the

[1] Specifically, two "leakage-safe" capital-income measures are constructed: one excluding deposit interest and one additionally excluding capital gains.

2007 training sample. The first-stage model is a random forest classifier (Breiman, 2001), selected after a systematic comparison of seven model classes—including penalised linear models, gradient-boosted trees, and rule-based regression—across multiple preprocessing specifications. Tree-based ensembles substantially outperformed linear approaches for this prediction task. Hyperparameters are tuned via cross-validation on a subsample of the 2007 population, and the final model is fitted on a larger subsample.

In the second stage, we estimate the conditional level function $m^{\text{Cash}}(\cdot)$ defined in Equation (7). The training sample is restricted to observations classified as deposit holders by the first-stage model. The outcome is the deposit balance in SEK, and the second-stage model is again a random forest regressor with separately tuned hyperparameters. The target is the raw balance level rather than a logarithmic transformation, since the object of interest is the level distribution of deposit wealth.

The main implementation choices are summarised in Table 2.

Table 2: Implementation details for the two-stage random forest

Choice	**Stage I: participation**	**Stage II: conditional level**
Estimator	Random forest classifier (`ranger`)	Random forest regressor (`ranger`)
Number of trees	1,000	1,000
Tuning sample	Stratified 10^5 subsample of the 2007 frame	Stratified 10^5 subsample of the 2007 frame
Tuning procedure	Five-fold cross-validation; 100-point grid	Five-fold cross-validation; 100-point grid
Final estimation sample	5×10^6 subsample	5×10^6 subsample
Selection criterion	ROC AUC	Mean absolute error
Outcome scale	Positive-balance indicator	Deposit balance in SEK, not log transformed

Among the most important predictors in both stages are predicted mortgage interest expense, the leakage-safe capital-income measure, total interest expense on debt, and non-financial disposable income—variables that collectively proxy for permanent income, leverage, and broader financial position.

4.2.4 Step 4: Rank-Normalised Prediction

A distinctive feature of the procedure is the treatment of the extensive margin in out-of-sample years. Raw KU20 participation rates vary mechanically with the reporting frontier and the interest-rate environment. Using a fixed probability cutoff from the 2007 classifier would therefore produce year-specific participation rates that reflect administrative reporting artefacts rather than true changes in deposit ownership.

We instead use the classifier as a ranking device. Let $\bar{s}^{\text{Cash}}$ denote the share of individuals in $\mathcal{R}_{2007}$ with positive observed deposits in the broad-reporting training sample. In the current construction,

$$\bar{s}^{\text{Cash}} \approx 0.598, \tag{9}$$

where the share is estimated over the 2007 training sample. For each year t, individuals are

sorted by their predicted participation probability $\widehat{\pi}^{\text{Cash}}(\mathbf{x}_{i,t})$, and the top $\bar{s}^{\text{Cash}}$ fraction are assigned as deposit holders. Equivalently, if

$$K_t = \left\lfloor \bar{s}^{\text{Cash}} N_t \right\rfloor, \qquad N_t = |\mathcal{R}_t|,$$

the K_t highest-scoring individuals in year t are assigned to the positive-balance group. This can be written as

$$\widehat{S}_{i,t}^{\text{Cash}} = \mathbf{1}\left\{\widehat{\pi}^{\text{Cash}}(\mathbf{x}_{i,t}) \geq c_t^{\text{Cash}}\right\}, \tag{10}$$

where c_t^{Cash} is the corresponding year-specific score threshold. If $\widehat{Q}_t^{\text{Cash}}(\cdot)$ denotes the empirical quantile function of the year-t participation scores, then c_t^{Cash} is equivalently represented by $\widehat{Q}_t^{\text{Cash}}(1 - \bar{s}^{\text{Cash}})$, up to the discreteness of the sample. By construction,

$$\frac{1}{N_t} \sum_{i \in \mathcal{R}_t} \widehat{S}_{i,t}^{\text{Cash}} \approx \bar{s}^{\text{Cash}}, \tag{11}$$

where the approximation reflects integer rounding and possible ties. The cross-sectional identity of predicted deposit holders may vary with observables across years, but the aggregate participation share is anchored to the uniquely informative 2007 training environment. This rank normalisation is an extensive-margin correction; it does not force yearly aggregate deposit sums to match any external total.

For predicted deposit holders, the second-stage regressor provides the balance estimate $\widehat{m}^{\text{Cash}}(\mathbf{x}_{i,t})$. For predicted non-holders, $W_{i,t}^{\text{Cash}} = 0$. In compact form, the final estimator is

$$W_{i,t}^{\text{Cash}} = \mathbf{1}\left\{\widehat{\pi}^{\text{Cash}}(\mathbf{x}_{i,t}) \geq \widehat{Q}_t^{\text{Cash}}(1 - \bar{s}^{\text{Cash}})\right\} \widehat{m}^{\text{Cash}}(\mathbf{x}_{i,t}). \tag{12}$$

The resulting individual-year predictions are assembled for each year from 1999 through 2015 and combined into a single panel.

5 Final Construction of the Target Variable

The output is an individual-year panel of imputed deposit balances covering the period 1999–2015. Each record contains a pseudonymised individual identifier, a calendar year, and the predicted end-of-year bank deposit balance $W_{i,t}^{\text{Cash}}$ in SEK. The unit of observation is the individual-year, and the panel covers every member of the resident population in each year. The sole output measure is $W_{i,t}^{\text{Cash}}$, the predicted end-of-year bank deposit balance for individual i in year t (in SEK), under the 2007 broad-reporting measurement concept.

The variable $W_{i,t}^{\text{Cash}}$ represents the predicted deposit stock under the 2007 broad-reporting measurement concept, obtained from a random forest trained on directly observed balances and transported to all years via the rank-normalised participation pro-

cedure described in Section 4.2. In years through 2007, the prediction and the directly observed balance coexist, even though the availability of observed balances is constrained by the reporting rules described above; from 2008 onward, the prediction is the only available estimate of individual deposit wealth. Several scope conditions follow from the estimation design. The estimator identifies individual deposits primarily through cross-sectional correlates learned in the 2007 environment and transported to other years under the maintained assumption that these correlates remain informative across the sample period. The lower tail of the deposit distribution—balances that fall below both reporting thresholds even in the broad regime—is only partially identified through covariate-based extrapolation. Yearly aggregate sums of predicted deposits are raw model-implied totals and are not calibrated to the national financial accounts.

A Glossary

Term	Definition
Kontrolluppgift	Tax control statement filed by Swedish financial institutions to Skatteverket, reporting interest income, balances, and related financial information for each account holder.
KU20	The specific control statement for interest income (*Kontrolluppgift — Ränteinkomst*), observed in the Kontrolluppgiftsregister (KURU) available via Statistics Sweden (2016b). Contains bank-interest income and, through 2007, end-of-year deposit balances.
KU25	The specific control statement for interest expense (*Kontrolluppgift — Ränteutgift*).
KURU	Kontrolluppgiftsregister — the register maintained by Statistics Sweden that consolidates all control statements for research use.
Förmögenhetsskatt	Swedish wealth tax, abolished effective income year 2008. Its abolition ended financial-stock reporting in KU20.
IoT	Inkomst- och Taxeringsregistret — the Income and Tax Register maintained by Statistics Sweden.
LISA	Longitudinell integrationsdatabas för sjukförsäkrings- och arbetsmarknadsstudier — longitudinal database linking health insurance, labour market, and demographic registers.
RTB	Registret över totalbefolkningen — the Total Population Register maintained by Statistics Sweden.
Kommun	Swedish municipality, the basic unit of local government and geographic classification.
Flyttflöde	Migration flow register maintained by Statistics Sweden, recording residential moves with dates and addresses.

Term	Definition
Flergenerationsregistret	Multi-Generation Register maintained by Statistics Sweden, linking individuals to biological and adoptive parents.
SCB	Statistiska centralbyrån — Statistics Sweden, the national statistical agency.
SEK	Swedish krona, the national currency.
